## **Abstract**

The mountain pine beetle (*Dendroctonus ponderosae* Coleoptera: Hopkins) epidemic currently taking place in western Canada is changing the structure of lodgepole pine forests. The altered landscape has created a new challenge for forest managers and requires mapping of the current forest conditions. The goal of this research is to develop a method for mapping the cumulative impact of intense beetle infestation on forest composition. By combining existing data sets on mountain pine beetle infestations, terrain, climate, and forest conditions with regression tree analysis we propose a method for mapping the spatial variability in mountain pine beetle caused pine mortality. To assess the methodology for large-area mapping of post-beetle forest composition, modelling was repeated at multiple spatial scales, and attributed with both fine scale field data and coarse scale forest inventory polygon data. The most important variables for predicting PPI are percent pine, stem density and the number of nearby infested trees . Accuracies of classifications were within +/- 25% percentage of pine infested between 54-91% of the models, and within +/- 15% percentage of pine infested between 9-64% of the models, depending on the spatial scale and input data used. The methodology is a flexible approach to modelling and mapping rapidly changing forest composition given operational data constraints.

Keywords : mountain pine beetle, regression tree, infestation severity, forest monitoring, forest mapping

## 1    **Introduction**

2    The mountain pine beetle, *Dendroctonus ponderosae* (Coleoptera: Hopkins), is a native  
3    species of many forest ecosystems in North America (Cole and Amman 1980).  
4    Periodically, beetle populations rise to epidemic levels impacting their environment with  
5    severe and spatially extensive infestation. Currently, the mountain pine beetle is  
6    affecting forests in western Canada on an unprecedented scale: over 9.2 million ha of  
7    forest are infested in British Columbia (B.C.) (Westfall 2007). The extent and severity of  
8    the current epidemic is due to two key factors. First, lodgepole pine (*Pinus contorta*  
9    Dougl. Ex Loud. Var. *latifolia* Engelm.) is the primary host for mountain pine beetle, and  
10    the amount of mature lodgepole pine in large contiguous stands has increased due to fire  
11    suppression (Taylor and Carroll 2004). Secondly, a warming climate has helped the  
12    success of beetle populations by reducing winter brood mortality and allowing the beetle  
13    to expand into previously unsuitable habitats (Carroll et al. 2004).

14

15    Most large-area maps of mountain pine beetle epidemics delineate the area impacted by  
16    the infestation providing no details of the spatial variability of the infestation magnitude  
17    or the impact to the forest (Wulder et al. 2006). These maps give the impression that the  
18    infestation is uniform in intensity and all trees within the infested region are dead. Such  
19    representations do little to assist forest managers tasked with setting priorities for  
20    harvesting and treatment. To aid management, updated forest inventory information is  
21    required in regions infested by the mountain pine beetle; knowing what trees remain is  
22    essential.

23

1 While information about the amount of remaining pine is necessary in the short term, the  
2 spatial extent of the infestation makes traditional approaches to forest inventory updating  
3 impractical due to the time and cost associated with collecting aerial photography or  
4 satellite imagery. However, existing forest health monitoring data, which quantify the  
5 location and magnitude of infestations, can be combined with forest inventories, which  
6 provide data on forest conditions prior to infestation, to model post-mountain pine beetle  
7 forest composition.

8  
9 Modelling the post-mountain pine beetle forest composition requires an understanding of  
10 the forest characteristics that lead to spatial variability in the amount of pine that remains  
11 in a stand. Susceptibility modelling by Shore and Safranyik (1992) has related stand  
12 characteristics to the likelihood of attack and damage by mountain pine beetles. Beetles  
13 have historically shown a preference for large diameter trees (Cole and Amman 1980).  
14 The mechanism by which beetles select large diameter trees is unknown, but the result is  
15 that when large trees are infested, brood production is enhanced the following year. Mass  
16 attacked trees having a diameter at breast height (dbh) larger than 25.4 cm are thought to  
17 be a source of beetles in the year following their infestation, while smaller trees act as  
18 infestation sinks (Safranyik et al 1974). Tree dbh is therefore an important variable in  
19 modelling forest damage caused by mountain pine beetle infestations (Shore and  
20 Safranyik 1992). Tree size increases with age, so stand age is also related to the  
21 susceptibility of a stand to mountain pine beetle attack. However, as lodgepole pine  
22 defenses (i.e., resin production) also vary with tree age, the likelihood of infestation starts  
23 to increase for trees greater than 60 years of age (Safranyik et al. 1974). Large trees with

1 thick, healthy phloem offer the most desirable hosts for mountain pine beetles, but  
2 typically are only infested when populations reach epidemic levels (Shore et al. 2006).  
3 Additional variables often used in modelling a stand's susceptibility to mountain pine  
4 beetle caused pine mortality are stand density, with beetles preferring moderately dense  
5 stands, and geographic location, which factors in latitude, longitude, and elevation (Shore  
6 and Safranyik 1992).

7  
8 The impact of infestation intensity and duration is also an important factor when  
9 modelling the amount of pine that will remain post-mountain pine beetle infestation, yet  
10 quantitative research in this area is more limited. Generally, the number of trees with dbh  
11 greater than 10 cm will be proportional to the total pine mortality. The size of the beetle  
12 population, and potential for brood production, are also related to the amount of pine  
13 mortality (Safranyik and Carroll 2006), although other factors complicate this  
14 relationship, especially at a sub-stand scale. Such factors include topographic variables  
15 (Amman 1973; Safranyik et al. 1973), the susceptibility of adjacent areas (Safranyik et al.  
16 1992), and long range dispersal (Furniss and Furniss 1972). Previous research has also  
17 suggested that beetle dispersal patterns may vary in different environmental conditions  
18 (Robertson et al. in press), so climatic and site characteristics may affect the infestation  
19 severity at different locations. The temporal aspect of the relationships between these  
20 factors, infestation severity and pine mortality is largely unknown.

21  
22 The goal of this paper is to develop an approach to map forest composition, or the  
23 amount of remaining pine after mountain pine beetle infestation, using existing data

1 sources. Regression tree classifiers are used to model percent pine infested (PPI) based on  
2 forest health monitoring data and variables known to influence the spatial variability of  
3 forest susceptibility to infestation (e.g., forest age, percentage, pine elevation). Given that  
4 ecological relationships are scale dependent (Levin 1992), we anticipate the input  
5 variables that will generate the most accurate regression tree model will vary depending  
6 on the spatial scale of model output (Woodward 1987; Nelson et al. 2006a). Therefore,  
7 the impact of spatial resolution of regression tree model is also explored. To ensure the  
8 method developed is operational, the effect of data on classification accuracy is also  
9 investigated by comparing the output of regression tree models that are generated using  
10 different data sets. The first data sets covers a large area but lacks attribute detail (the  
11 forest inventory), while the second data set is available for only a small area but has more  
12 detailed attribution.

## 1    **Study Area**

2    The research study area is the Morice Timber Supply Area (TSA), in west central (54°  
3    24' N 126° 38' W) British Columbia (Figure 1). The current epidemic in the Morice area  
4    dates back to the early 1990s (Nelson et al. 2006b). Lodgepole pine cover approximately  
5    50% of the forested landbase in the TSA, and the northern region approximates the  
6    northwestern range of mountain pine beetle suitable habitat. Beetle populations are  
7    known to be univoltine throughout the TSA, meaning beetles emerge once per year in  
8    late summer. Other dominant species include hybrid white spruce (*Picea egelmannii*  
9    (Parry) *x glauca* (Moench) Voss) and subalpine fir (*Abies lasiocarpa* (Hook.) Nutt). The  
10    TSA lies primarily in the Sub-Boreal Spruce (SBS) Biogeoclimatic Ecosystem  
11    Classification (BEC) zone (although high elevations are in the Englemann Spruce –  
12    Subalpine Fir zone). The BEC system classifies landscapes based on site and climatic  
13    features. Zones are areas influenced by the same regional climate. Subzones, divided  
14    into zonal (typical), and variant (atypical), are geographically related ecosystems (Eng  
15    and Meidinger 1999). Within the SBS, there are two subzones: Moist Cold (SBSmc) at  
16    moderate elevations, and the warmer Dry Cool (SBSdk) subzone at lower elevations  
17    (Meidinger et al. 1991).

18

19

## **Data**

### **Aerial Surveys**

Mountain pine beetle monitoring in the Morice TSA has been extensive. Heli-GPS surveys, undertaken annually since 1995, provide yearly datasets of outbreak progression. Through helicopter based surveys the locations of infested trees are recorded with GPS points, and the number of infested trees estimated (Nelson et al. 2006b). Crown foliage discolouration is used as a proxy for infested trees. Once a tree is infested, it takes approximately one year for the foliage to turn from green to red. Two years after infestation an attacked tree typically appears grey as the needles have dropped off (Safranyik et al. 1974). The area of infestation represented by each GPS point recorded in a helicopter survey varies, but is estimated to have a maximum area of a circle with a 100 m radius (Nelson et al. 2006b). Field verification of heli-GPS data has found that estimates at each point location are accurate to within 10 trees, 92.6% of the time (Nelson et al. 2006b). A limitation of heli-GPS surveys is that all locations are mapped as clusters of trees (i.e., one point with an attribute for number of trees), when in reality, the spatial distribution of infested trees may be clustered or dispersed (Wulder et al. 2006). This type of representation is used because mountain pine beetle attacked trees are typically found as 'spot infestations', due to the pheromone dynamics associated with mass attacking large trees (see Geiszler et al. 1980), however at epidemic population levels, infestations occur as large contiguous patches (Safranyik and Carroll 2006). One approach to dealing with this source of uncertainty is to aggregate the counts of the damaged trees over a larger spatial area to form a measure of infestation density (Nelson et al. 2006b).

1

## 2 **Field Surveys**

3 Detailed data on mountain pine beetle infested forest composition were collected through  
4 plot-based field surveys that were undertaken in the Morice TSA during the summer  
5 months of 2003 and 2004. Plots were established at locations identified as infested  
6 during the heli-GPS surveys. Thus, all plots were located where mountain pine beetles  
7 had been present for at least one year. Plots were circular with an area of 200 m<sup>2</sup> (or .02  
8 ha). In each plot, all trees with dbh > 10 cm were surveyed, and trees were categorized as  
9 healthy pine, newly attacked pine (green foliage), previously attacked pine (red foliage),  
10 dead pine (grey foliage), or non-pine. Previously attacked and dead pine were summed  
11 and divided by the total number of pine trees in the plot, giving the percentage of pine  
12 infested (PPI). Recently attacked trees with green foliage were excluded as they can not  
13 be surveyed aerially. Within the Morice TSA, 231 plots were established in 2003, and  
14 144 were established in 2004, totaling 375 locations where the percentage of pine  
15 infested by mountain pine beetles is known.

16

## 17 **Forest Inventory Database**

18 British Columbia Ministry of Forests' inventory is the primary data set available for  
19 characterizing forest conditions across the province. The forest inventory polygon (FIP)  
20 attributes used in this study were forest age, percentage pine, and dbh. Forest inventory  
21 data are primarily generated via aerial photo (1:15,000) interpretation (Leckie and Gillis  
22 1995) and were last updated in the Morice TSA in the mid 1990s. Stand age is the age, in

years, of the forest stand on the date of polygon classification, and is based on ring counts from a bored core or is estimated from aerial photographs. Tree species and percentages are given for the six most dominant forest species. The dominant tree species, occupies the largest percentage of the stand. Both the species and the percentage of the stand composed of this species are recorded. In the forest inventory, dbh is reported as the quadratic mean stand dbh and is calculated based on forest age and site index. The quadratic mean is the square root of the arithmetic mean of squared values and gives greater weight to large trees. Typically, the quadratic mean is used for calculating stand dbh as it relates to other forest characteristics more meaningfully than does the arithmetic mean (Curtis and Marshall 2000).

## **Ancillary Datasets**

Additional ancillary datasets were available for the Morice TSA and used in this study. A digital elevation model (DEM) with grid cells of 100m by 100m was used to derive topographic variables (Province of British Columbia 1996). The DEM was created from 1:20,000 scale Terrain Research Information Management data using linear interpolation and is accurate within 10 m (Province of British Columbia 1996). A dataset of BEC zones was obtained for the Morice TSA. This dataset represents the BEC zones and subzones present in the study area. In previous work, subzone classifications, SBSmc and SBSdk, have shown marked trends in movement patterns indicative of mountain pine beetle dispersal processes (Robertson et al. in press).

## 1    **Methods**

2    Our methodological approach to mapping forest composition is based on the use of  
3    regression tree classification, a method capable of modeling complex, nonlinear  
4    relationships. We used ArcGIS<sup>®</sup> software (ESRI 2005) for all GIS operations and  
5    mapping, and used R (Ihaka and Gentleman 1996) for all statistical analysis. Research  
6    methods are categorized into four groups. First, the data pre-processing methods are  
7    described. Secondly, the regression tree classification method is outlined. Thirdly, the  
8    approach used for accuracy assessment is described. Finally, the methods applied to  
9    assess the impact of the regression tree model spatial resolution and input data on model  
10   accuracy are presented.

11

### 12   **1) Data and Data Pre-Processing**

13   Variables used with regression tree classification reflect the infestation conditions, terrain  
14   and climate factors, and forest conditions (Table 1). The heli-GPS monitoring data was  
15   used to incorporate infestation magnitude and duration into the model of remaining pine  
16   forest. The intensity of infestation at each location was estimated by counting the  
17   number of trees killed by mountain pine beetles recorded in the heli-GPS data within a  
18   2000 m radius of each plot centroid (DEAD). This distance threshold is a conservative  
19   estimate of the maximum short range dispersal distance of a mountain pine beetle  
20   through unsuitable habitat (Barclay et al. 2005). This variable should therefore be an  
21   indicator of the size of the local beetle population. Infestation duration (ID) was also  
22   derived for each plot centroid in the study area. For each point, heli-GPS points within

1 200 m were located. The first year that a point was found within 200 m of the grid cell  
 2 centroid was identified as the beginning of infestation at that location. The 200 m  
 3 threshold was used here to ensure that beetles were within a distance immediately within  
 4 attack range (Safranyik et al. 1992).

5  
 6 In order to incorporate both infestation intensity (the number of dead trees) and  
 7 infestation duration, an index called impact factor (IF) was calculated for each plot. The  
 8 IF was calculated as the number of dead trees divided by the ID at a particular location.

$$9 \quad [1] \quad IF = \frac{\sum_{i=1}^j DEAD}{(j-i)}$$

10 Where  $i$  is the first year of the infestation data, and  $j$  is the latest year of infestation data.  
 11 The IF was used to be representative of different stages of infestation. For example, with  
 12 a finite number of trees at a location, infestation at a particular intensity can be only be  
 13 sustained until all trees are infested. The IF is designed to differentiate new, intense  
 14 infestations (high impact) where beetles have perhaps migrated from adjacent areas, from  
 15 older infestations where local populations have built up from incipient levels over several  
 16 years (medium / low impact). From an ecological perspective, high impact infestations  
 17 may represent beetle population increase in an area due to dispersal, while low impact  
 18 infestations are increasing due to environmental factors.(Moran effect). In reality, these  
 19 influences on beetle populations are often difficult to decompose.

20  
 21 To include the impacts of terrain in the post-beetle forest composition model, a DEM was  
 22 used to quantify elevation (EL) and to calculate the slope or inclination (SLP) and aspect

or orientation (ASP) of the surface. Slope has previously been identified as an important variable for predicting locations of mountain pine beetle infested trees at a landscape scale (Wulder et al. 2006b). Additionally, southern aspect sites are generally more productive for lodgepole pine than other aspects, and have been found to be associated with newly established infestations (Safranyik et al. 1974). A cosine transformation of aspect provided a linear scale for the 'northness' of the slope direction from -1 (due south), to +1 (due north). A sine transformation of aspect provided a linear scale for the 'eastness' of the slope orientation, from -1 (due west) to +1 (due east). Previous research has successfully used these transformations for regression modelling of aspect (Schwarz et al. 2003).

Climatic and terrain impacts were included in the model by calculating direct solar radiation (SWR) using the methods of Kumar et al. (1997). Consideration of terrain through solar radiation was useful given the complex terrain of the study area, where elevation ranges from approximately 545 m to 2730 m over an area of 1.5 million ha. Direct solar radiation has been demonstrated to be a significant variable for predicting locations of previously infested trees (red foliage) in pine stands (Coops et al. 2006). Calculations for potential direct solar radiation require parameters for terrain (DEM), latitude, day of the year, and time interval at which to make calculations. Kumar et al. (1997) suggest that short time intervals have greater accuracy, so calculations were made every 30 minutes. Consequently, for computational efficiency, two summer days (Aug. 1-2) were selected to be representative of spatial variation in direct solar radiation. These

1 dates approximate the period of mountain pine beetle emergence in the study area and the  
2 season when incoming solar radiation is greatest.

3  
4 Variables on forest conditions known to influence forest susceptibility to the mountain  
5 pine beetle were also included. Data on forest age (AGE) was determined from the forest  
6 inventory data. Plot percentage pine (PPERP) and stem density (DENSE) were acquired  
7 from field plots. When assessing the impact of different input data on regression tree  
8 output using large area data sets with more general information, stand percentage pine  
9 (PERP) was used instead of plot percentage pine. Mean stand quadratic dbh (QDBH) was  
10 also utilized from the forest inventory data, and no density data were available. The true  
11 value for the variable being modeled, the percentage of pine infested (PPI), was always  
12 determined from the plot data.

## 14 **2) Statistical Analysis: Regression Trees**

15 Regression tree (RT) modelling was used to construct models of the proportion of  
16 infested trees (Breiman et al. 1984). The regression tree approach has traditionally been  
17 employed in fields such as medical diagnosis (Ridley et al. 1998) and machine learning  
18 (Quinlan 1986), but is increasingly being used in ecological analyses (De'ath and  
19 Fabricius 2000). There are attractive advantages of regression tree analysis over  
20 traditional regression: distributional assumptions of variables are not required, complex  
21 interactions between variables can be accurately handled, and the methods are robust  
22 with respect to outliers and missing values, all of which are common in ecological data  
23 (Prasad et al. 2006). Some examples of regression tree modeling applied in forestry

include predicting tree mortality (Dobbertin and Biging 1998; Fan et al. 2006) and forest health applications (Rosso and Hansen 2003; Negron and Popp 2004; Coops et al. 2006).

The RT approach works by recursively partitioning response variables into mutually exclusive groups. This process is referred to as “growing” the classifier (tree). At each stage, the predictor variables are assessed to determine which variable can be used to split the dependent variable into the two most homogeneous groups. The variable that achieves the most homogeneity is used to split the data, and a node is generated with two sub-branches. Each node represents the partition, among a number of candidate partitions in the set of predictor variables, that maximizes the homogeneity of the two resultant groups. The RT analysis tries to accurately classify the response variable into groups that minimize within-group variance and maximize between-group variance. Additionally, a RT should be sufficiently small (size measured by the number of final classes, called terminal nodes), so that the partitioning of the data is meaningful, and useful for prediction on new data. The general methodology proposed by Breiman et al. (1984) for growing an optimal RT is to continue splitting the response to form a very large RT, a model that has a large number of binary splits, and then reduce or prune nodes, using cross validation to select an optimal RT size.

Deviance, the sum of squares about each candidate group mean, was used as the partitioning criterion to grow trees into sequences of binary decisions on the predictor variables. The mean deviance across all terminal nodes, residual mean deviance (RMD), was used to assess the fit of a RT to the data (Ripley 1996). The RMD quantifies the

1 average heterogeneity in the terminal node classes. Minimizing the RMD is a way of  
2 reducing group impurity, but does not select optimal trees because it does not consider  
3 tree size. The RMD is biased downward: it will always be minimized with the largest  
4 trees because the terminal node classes will be composed of the fewest observations  
5 (Breiman et al. 1984). This is analogous to stepwise linear regression, where adding  
6 variables always increases the  $R^2$  for the model. Pruning addresses this problem for RTs  
7 by estimating the 'unbiased deviance'.

8

9 We used ten-fold cross validation as a pruning method to obtain estimates of the true  
10 deviance for each tree size ('honest estimates' in Breiman et al. 1984). In the cross  
11 validation procedure, the dataset is split into ten groups, RTs are grown based on nine  
12 groups and tested on the 10<sup>th</sup> group. This is performed on each of the groups separately  
13 and deviances are averaged over all groups. Following the procedure recommended for  
14 prediction by Ripley (1996), we repeated the cross validation ten times. The largest and  
15 smallest RTs that minimized the cross validated deviance were selected for testing. We  
16 used two sizes as a way of balancing our objectives of description and prediction.

17

18 When the RT model was implemented in this study, it was carried out using a random  
19 sample of 66% of the field plot locations for 2003 and 2004 ( $n = 254$ ). Once rules were  
20 generated for field plots, which had known PPI, the model could be applied to classify  
21 the entire study area using the data available. Each time a RT model is generated all  
22 variables are used as input; however, only some are utilized by the model for  
23 classification (Table 2).

1

### 2 **3) Accuracy Assessment**

3 The 34% of data (n = 121) not used for building the RT model were reserved for  
4 assessing the accuracy of the model output. Accuracy was categorized as +/- 25% and  
5 +/- 15%. Observed and predicted values of pine mortality were also converted into the  
6 intensity classes used in province wide assessments of forest damage in B.C. (see  
7 Westfall 2007). Additionally, prediction maps were assessed visually.

8

### 9 **4 Assessing the Impact of Model Resolution and Input Data**

10 To assess the impact of spatial scale on our RT model output, analysis was repeated with  
11 model output resolution equal to the original field plots (0.02 ha), as well as, 100 ha grid  
12 cells, 2500 ha grid cells and 10000 ha grid cells. These resolutions represent potential  
13 cell sizes for mapping at the landscape, regional and national levels. The mean forest  
14 inventory polygon area in the Morice TSA is 20 ha, so grid cell sizes were selected larger  
15 than this threshold to avoid repeated observations from the same polygon.

16

17 To assess our methodology for application in large-area mapping, we investigated the  
18 impact of data on the analysis by using both field plot and large-area FIP data sets to  
19 attribute the RT model. A key difference in these data sets is that for the plot data,  
20 percentage of pine and stem density were calculated based on field observations within  
21 0.02 ha plots. In the FIP data, percentage pine is estimated for forest inventory polygons  
22 where pine is included as one of the six dominant species. Percentage pine  
23 measurements will differ between the FIP and plot data for two reasons. Firstly, the

percentage pine in the FIP data is estimated, based on photo interpretation and ground-truthing, and is therefore subject to greater error than the plot data. Secondly, the FIP data are collected at a stand scale while field data are collected for plots that are sub-stand in size. As such, one would expect forest attribute values from these two data sources to differ. Another important difference between FIP and field data is that density information is only available for the field plots. For analysis conducted with the FIP data a surrogate variable used for susceptibility modelling, quadratic mean dbh, is used (Nelson et al., 2006a).

For field plots, 78% of the random sample (198 of 254) used for training RTs were located in unique forest inventory polygons. For RTs generated from plot data, the values for each variable represent the mean of the values recorded in the field plots, while for RTs based on FIP data the values represented the mean of the all of the values within the grid cell. For example, in one 100 ha grid cell which contained three field plots, the plot RT value for elevation would be the average of the elevation values at all three plots, while for FIP RT, the elevation would be the average of all DEM values within the grid cell (i.e., 100 100m pixels). This is illustrated in Figure 2. In all regression trees, the dependent variable was the plot level PPI.

## 1     **Results**

### 2     **Phase 1: Modelling infestation intensity for field plots.**

3     For plot RTs at the 0.02 ha scale, a RT was grown to an initial size of 17 terminal nodes.  
4     Residual mean deviance for the initial RT was 0.03. Cross validation selected optimal  
5     tree sizes in the range of three to six terminal nodes. Over all of the test sample plots (n =  
6     121), the six node RT predicted infestation intensity within 25% of the actual value for  
7     60% of the data. The three node RT predicted within 25% accuracy for 58% of the data  
8     (Table 3a). Classes with a very high mortality due to infestation tended to be  
9     underestimated due to the averaging of class values that occurs when RTs are pruned.  
10    When plots with greater than 85% infestation were excluded from the test samples,  
11    accuracies increased to within 25%, 70% of the time, for both the three and six node RT  
12    (Table 4a).

13

14    In plot RTs classified at the 0.02 ha scale the most important variables for partitioning  
15    PPI were plot density (DENSE) and the percentage of pine observed in the field plot  
16    (PPERP). The six node RT is presented in Figure 3. The left side reveals that plots  
17    where stem density is below 375 stems / ha are classified as either 100% infested, or 69%  
18    infested, depending on the percentage of the trees that are pine being below or above  
19    45%. The right side decisions reveal that the lowest class, 21% dead pine, is found where  
20    greater than 40% of the plot's trees are pine, density is above 375 but below 675 stems /  
21    ha, and fewer than 132 dead trees are within a 2 km radius of the plot.

22

## **Phase 2: Modelling infestation intensity using regression trees and operational data.**

Using FIP and topographic data averaged to a 1 km grid cell resolution, RTs were grown to classify average plot infestation level for plots within each grid cell. The results of this analysis are presented as dataset FIP-2 in Table 3b. The initial RT had 21 terminal nodes,  $RMD = 0.032$ . Cross validation selected optimal sizes within the range of 4 ( $RMD = 0.056$ ) to 9 nodes ( $RMD = 0.046$ ). Important variables for classification of infestation level were IF, AGE, PERP and SWR (Table 4). The nine node RT is presented in Figure 4. Percentage of pine was less important for variable splits for FIP data compared to the plot data. It is worth noting that the Pearson's correlation coefficient between the observed plot percentage of pine (PPERP) and the percentage of pine (PERP) reported in the forest inventory polygon the plot was located within indicated only a moderate association ( $r = 0.32$ ).

When RT estimates were converted to the forest health rating classes, accuracy of the six node RT was 19%, and 31% for the three node RT (Table 2b). The 9 node RT was accurate to within 25% at 48% of the test samples. The 4 node RT predicted moderately better, at 55%. Prediction accuracy increased to 56% and 66% when the highest levels of infestation were excluded (Table 4b).

## **Phase 3: Assessing the impact of spatial resolution on regression tree variables and model accuracy.**

Generally, as the grid cell resolution became coarser, and large geographic areas were aggregated, accuracies of the regression trees increased. This was evident in both the plot

1 data and the FIP data (Table 3a and 3b). Highest overall accuracies were achieved using  
 2 a spatial extent of 10 km (or 10 000 ha). However, at high levels of aggregation,  
 3 regression trees also tended to become unstable. For example, using FIP data represented  
 4 with a cell size of 10 000 ha, infestation levels were predicted within 15%, 48% of the  
 5 time using a 4 node tree, yet using the 6 node tree on the same data reduced the accuracy  
 6 to 9% (Figure 2b). Also, at the 2500 ha resolution, the FIP data could not generate a tree  
 7 better than random, so the unpruned regression tree is presented as FIP-3. For both the  
 8 PLOT and FIP data, the 0.02 ha and 100 ha resolutions appear to have achieved the best,  
 9 most robust results.

10

11 Across all spatial scales, for the plot data, DENSE appears to be the most important  
 12 variable classifying infestation intensity (Table 2). It is intuitive that at a tree level,  
 13 greater density will reduce the proportion of trees that are killed at any location.  
 14 However, density information is rarely recorded in operational forest inventory data, such  
 15 as the FIP data used in this analysis. Interestingly, our surrogate variable for density,  
 16 stand quadratic mean dbh, was not included in any of the FIP RTs. The most common  
 17 variable used in the FIP RTs was PERP. Other variables common to RTs computed with  
 18 plot and FIP data include: DEAD (include in 9 out of 15 trees), IF (6/15), EL (6/15),  
 19 SWR (5/15), and ID (3/15).

20

## 21 **Mapping the percentage of pine remaining in the Morice TSA**

22 Due to data availability, mapping the percentage of pine remaining in the Morice TSA,  
 23 required the use of the FIP RTs. We selected 100 ha grid cells as an appropriate spatial

grain for mapping. The RTs at this scale were also composed of appropriate rules for mapping. For accuracy levels other than the FHI classes, the 4 node RT performed better. We used this RT for mapping pine mortality across all of the Morice TSA. We applied the modelled PPI values to the FIP data to summarize the percentage of pine remaining in each forest inventory polygon. This map is presented in Figure 5. Additionally, Figure 6 presents the percentage change caused by mountain pine beetle between 1995 and 2004.

## **Summary and Conclusions**

Identifying the changes occurring in forests impacted by epidemic mountain pine beetle populations is crucial for forest management. The approach to mapping forest composition taken in this research was useful for identifying the important variables in predicting spatial variation in mountain pine beetle caused pine mortality. These were selected from a range of variables (Table 2) known to impact a forest's susceptibility to mountain pine beetle infestation. Across all RTs, the important predictor variables for partitioning PPI were percentage pine and the number of dead trees within a 2 km radius. Lower numbers of pine trees surrounded by high numbers of dead pine trees naturally corresponds to a high level of pine mortality. Interestingly, at smaller spatial grains IF was also an important variable for classifying the percentage of pine mortality. For example, in the FIP RTs, IF was included in all RTs computed at spatial resolutions of 0.02 ha and 100 ha (Table 2). This suggests that locally, IF may be a useful measure of fast moving, highly intense infestations. However, at broader spatial scales, perhaps larger scale climatic and environmental variables are more relevant for overall pine

mortality, such as SWR and EL (i.e., FIP RT at 10 000 ha). Additionally, as local heterogeneity was smoothed out at larger spatial grains, the predictive power of the RTs improved. Considering the large spatial and temporal extents of the infestation in the Morice TSA, it is perhaps not surprising that the accuracy of RTs for prediction improved as the spatial grain was increased (i.e., see Wiens 1989). As larger areas of forest are grouped into individual grid cells, the variation of forest conditions within each grid cell increases, and variation between grid cells declines. It is important to note that patterns observed, and predicted at larger spatial grains, may not necessarily hold at finer spatial grains because mountain pine beetle spatial processes operating *within* and *across* forest landscapes may differ. An explicit acknowledgement of pattern and scale is important when interpreting model results.

RT analysis provided an approach to modelling the impact of environmental and population variables on mountain pine beetle caused pine mortality that is flexible enough to be applied for operational, large-area mapping. The decision rules output from RT analysis are easily implemented for forest planning, especially RT results that leverage existing data sources, such as FIP, DEMs and heli-GPS data. All of these variables can be derived within standard GIS software and commonly available data sources.

Figure 4 highlights one of the shortcomings of the RT modelling, namely that the output rules cannot classify outside the range of the input values. In the Figure 4 RT, all locations where IF is less than 47.22 will be classified as 38% infested (PPI). In

1 situations where beetles are not present, the IF will be 0 and the PPI will also be 0.

2 Therefore, care should be taken when applying the rules to new data for prediction that  
3 the input data are fully representative of all locations being classified. In this analysis,  
4 RTs were grown on data where beetles were known to be present for at least one year, so  
5 the results of RT rules are limited to similar areas.

6  
7 The results of the FIP RTs indicate that for operational data two key issues are important  
8 when modelling forest composition using RT. Firstly, an explicit consideration of spatial  
9 scale is critical to understand the impact of different scale dependent processes on the  
10 dependent variable. In our analysis, environmental and climatic variables, such as EL  
11 and SWR were more often important at larger spatial scales, while a local population  
12 variable (IF) was more important at smaller spatial grains. A major limitation to our RT  
13 analysis at large spatial grains was that infestation severity (PPI) information was not  
14 known for larger grid cells, so was calculated as the average of the PPI values recorded in  
15 the plots within each grid cell. This is a common problem in large-area research because  
16 of the difficulty associated with making accurate measurements across large,  
17 heterogeneous landscapes (Nelson et al. 2006a). Secondly, the impact of data quality and  
18 availability is also important. For example, while DENSE was always the most  
19 important variable for plot RTs (which is expected as it is highly correlated with PPI), the  
20 surrogate variable for plot RTs, QDBH, was never included in cross-validated RTs. This  
21 suggests that QDBH may be a poor surrogate for stem density and should be used as such  
22 cautiously.

1 Accuracy of classifications were within +/- 25% percentage of pine infested between 54-  
2 91% of the time, and within +/- 15% percentage of pine infested between 9-64% of the  
3 time, depending on spatial scale and data of the regression tree. RT accuracy for  
4 predicting forest health intensity classes ranged from 22-61%. All RTs performed better  
5 when the top 15% of the most intensely infested areas were excluded from the analysis  
6 (Table 4a-b). For operational mapping, the 100 ha scale, or 1 km by 1 km grid cells, are  
7 appropriate for landscape scale mapping of infestation severity, given the accuracy and  
8 scale of the forest inventory data.

9

10 The objective of this research was to develop and assess a methodology for large-area  
11 mapping of the impact of intense beetle infestation on forest composition. In this respect,  
12 our analysis has shown that using regression tree modelling is a flexible approach to  
13 mapping the changing characteristics of forests, given operational data constraints. This  
14 methodology allowed us to determine important variables modelling the spatial variation  
15 of infestation impact on forest composition, and provided a means for mapping the  
16 response variable. The map of the amount of change in percentage pine due to mountain  
17 pine beetle caused pine mortality (Figure 6) demonstrates the utility of visualizing the  
18 model results across the landscape, and allows for intuitive interpretation of spatial  
19 variability over a large area. Thus, we feel that the methodology, when applied at an  
20 appropriate spatial scale, is a useful approach for large area, operational forest mapping.

21

22 In addressing our objective, variables useful for modelling post-beetle forest composition  
23 were identified. Although all variables input to the model were known to impact spatial

variation in infestation severity, only some were used by the RT classifier for modelling. The variables identified as important for classification of infestation severity were mainly stem density, percentage pine, number of dead trees within 2 km, and IF. These variables all relate to either the number of susceptible trees, or the number of already infested trees nearby. Other variables known to influence the impact of mountain pine beetle to a forest, such as aspect, slope, BEC classification, and dbh were rarely or never used by the RT models. What appears to be important to the development of severe beetle infestations is the availability of adjacent suitable hosts, which facilitate short range dispersal. In addition to other “beetle proofing” silviculture practices such as varying age class distribution and uniform spacing, planning future forest composition to be less susceptible to severe infestation should perhaps focus on interspersing patches of susceptible trees by at least distances greater than 2 km. While this would not stop the spread of the infestation, as the actual short range dispersal distance is likely to be variable, and wind-driven dispersal would still occur, it would at a minimum mitigate the effect of high impact infestations (intense, fast moving).

<b>Variable</b>	<b>Description</b>	<b>Description</b>
DEAD	# of dead trees within 2 km radius	The number of mountain pine beetle attacked trees within a 2 km radius.
ID	Infestation duration	The length of time since the first mountain pine beetle attacked tree was found within a 200 m radius of the sample plot.
IF	Impact factor	The number of mountain pine beetle attacked trees within a 2 km radius divided by the length of time beetles have been present.
EL	Elevation	Elevation as recorded in the digital elevation model.
SLP	Slope inclination	Surface inclination calculated from the digital elevation model.
ASP	Aspect orientation	Surface orientation calculated from the digital elevation model.
SWR	Short wave radiation	Direct shortwave radiation, in $\text{kJ/m}^2$ at 30 minute intervals.
AGE	Stand age class	Age class of the stand recorded in the forest inventory.
PPERP*	Percentage pine in the plot	The actual percentage of pine within the field plot.
DENSE*	Stem density in field plots (stems / ha)	The stem density within the field plot is directly related to the amount of pine infested when combined with percentage pine, and information about the local beetle population.
QDBH**	Stand quadratic mean dbh	Stand scale quadratic mean dbh is often used as a surrogate variable for stand density.
PERP**	Percentage pine in the stand	At a stand scale, the estimated percentage of pine extracted from forest inventory polygons.

**Table 2.** All regression trees used in the analysis.
